The Gastrointestinal Tract in HIV-1 Infection: Questions, Answers, and More Questions!

Recent studies in HIV-1 infected individuals have demonstrated that the gastrointestinal (GI) tract is preferentially and profoundly affected during acute and chronic HIV-1 infection. These findings shed light on early postinfection events at mucosal sites. In addition, they raise important questions regarding the long-term impact of immune depletion within the GI tract on HIV-1 pathogenesis. The following review summarizes recent studies that have brought the GI immune system to the forefront of HIV research.

The Gastrointestinal Tract as an Immunologic Organ

The primary function of the GI tract is digestion, absorption, and assimilation of nutrients (Table 1). To maximize the efficiency of digestive function, the GI tract has evolved such that it has the largest surface area among all organs. In fact, the 400 m² surface area of the GI tract is about 200 times larger than the surface area of the entire skin.1 Having such a large surface in close proximity to the external environment necessitates that a large complement of immune cells—both innate and adaptive—be deployed at mucosal surfaces. Indeed, GI-associated lymphoid tissue constitutes the largest immune compartment in the body. It is estimated that T cells associated with the small intestinal epithelium alone may account for more than 60% of the total body lymphocytes.2

| TABLE 1. Salient Features of the Gastrointestinal Immune System |
| The largest reservoir of immune cells in the body. |
| Organized into: |
| • Immune inductive sites—PPS (small intestines), lymphoid aggregates (large intestines), and MLNS (both small and large intestines). |
| • Immune effector sites—LPLS and IELS. |
| Antigen is presented via various pathways to inductive sites in the GI tract, including the uptake of antigen by specialized “M” cells. |
| • T-cell education is initiated in immune inductive sites such as MLNS. |
| • “Homing” signals are imparted to T cells, likely within the immune inductive sites, following which, T cells egress into systemic circulation and return to the effector compartment of the GI tract to discharge their effector function. |

GI indicates gastrointestinal; PPS, Peyer’s patches; MLNS, mesenteric lymph nodes; LPLS, lamina propria lymphocytes; IELS, intraepithelial lymphocytes.

Immune cells in the GI tract are organized into distinct anatomic and functional subcompartments (Figure 1).3 These are classified as immune inductive sites, considered as sites of T cell education, and immune effector sites, where T cells neutralize foreign antigens—both microbial and nonmicrobial. Immune inductive sites are comprised of Peyer’s patches (PPS) and mesenteric lymph nodes (MLNS). Peyer’s patches have the anatomic appearance of secondary lymphoid organs, with clearly defined T- and B-cell–dependent areas. A single layer of epithelial cells separates the PPS from the intestinal lumen. This epithelial cell layer contains specialized cells called M cells in addition to conventional enterocytes. It appears that the function of M cells is transport of antigen into immune inductive sites resulting in initiation of T-cell education and maturation. It is believed that further maturation of T cells continues within MLNS that drain GI mucosal tissue. It is thought that MLNS are the crossroads of systemic and mucosal immunity. Within the MLNS, lymphoid cells from mucosal and systemic immunity interact, T-cell maturation continues, and it is likely that critical issues of gut homeostasis are determined as outlined below.

Immune effector sites may be thought of as the battlegrounds where terminally differentiated T cells perform effector function, neutralizing antigen and protecting the host against invading pathogens. Effector site lymphocytes can be subclassified into lamina propria lymphocytes (LPLS) and intraepithelial lymphocytes (IELS). As detailed below, LPLS have a unique phenotype—these cells are terminally differentiated effector T cells that have pathways of stimulation that are different from peripheral blood T cells. For example, it appears that LPLS proliferate at relatively low levels in response to antigen or other T-cell antigen receptor (TCR)–dependent stimuli.4-5 In contrast, IELS secrete large amounts of effector cytokines, such as IFN-γ, IL-4, and IL-5,6 and have a unique requirement for CD8-dependent pathways of activation.7 The IELS also constitute a unique population of lymphocytes in the body. More than 80% of IELS are CD8⁺ and a substantial proportion of IELS express the CD8αα homodimer in contrast to the CD8αβ heterodimer expressed on a majority of peripheral blood CD8⁺ lymphocytes.8,9

It is believed that after encountering antigen in the inductive compartment, lymphocytes egress into the systemic circulation, where further maturation and differentiation occurs. These differentiated, effector memory (TEM) cells migrate back to the effector sites and await stimulation to discharge effector function.10,11 This is regulated by the coordinated interaction of various cell surface molecules on the T cell with their respective ligands on the surface of vascular endothelial cells in the GI tract. T cells expressing α4β7-integrin,12 αEβ7-integrin13 and C-C chemokine receptor 9 (CCR9) (Figure 1)14 are perhaps the best characterized in terms of homing potential to the GI tract. The ligand for α4β7-integrin is mucosal vascular adhesion–addressin cell-adhesion molecule 1 (MADCAM-1),15 which is expressed under steady-state conditions by endothelial cells in the GI tract and associated lymphoid tissues.16 Intestinal intraepithelial lymphocytes and a subset of LPLS express αEβ7-integrin, the ligand for which is E-cadherin,17 located on intestinal epithelial cells. A subset of circulating α4β7⁺ T cells selectively express CCR9. The ligand for CCR9, CC-chemokine ligand...
The effect compartment consists of lamina-propria lymphocytes and the IELS. M cells act as specific entry ports for antigen, facilitating the uptake of luminal antigens and their subsequent delivery to the initiation compartment of the organized lymphoid tissues, including the PPS and the MLNs. Naive T cells activated in the PPS and MLNs upregulate expression of the integrin $\alpha_4\beta_7$, which interacts with MADCAM1, expressed on the endothelium of the intestinal-tissue HEVs, thereby facilitating homing to the mucosal effector compartments. The chemokine CCL25, which is produced by epithelial cells of the small intestine, is also involved in the migration of lymphocytes to the intestinal mucosa, and its receptor, CCR9, is expressed by almost all lymphocytes of the small intestine. The integrin $\alpha_4\beta_7$ is expressed by IELS and interacts with E-cadherin, which is expressed by the epithelial cells, facilitating tethering of the IELS to the intestinal epithelium.

IELS indicates intraepithelial lymphocytes; PPS, Peyer’s patches; MLNs, mesenteric lymph nodes; MADCAM1, mucosal addressin cell-adhesion molecule 1; HEVs, high endothelial vessels; CCL25, CC-chemokine ligand 25.

25 (CCL-25), is constitutively and selectively expressed by epithelial cells of the small intestine. Expression of G1-specific homing markers is induced following priming of T cells in MLNs and other secondary lymphoid organs draining the GI tract. Recent data demonstrate that MLN resident dendritic cells are necessary and sufficient in the induction of G1-associated homing receptors.

Susceptibility of the Gastrointestinal Tract to HIV-1 Infection

The majority of HIV transmissions worldwide occur across a mucosal surface such as the anorectal mucosa, vaginal mucosa and, less frequently, the oral mucosa (Table 2). HIV-receptive cells have been found in the lamina propria of rectal, cervicovaginal, foreskin, urethral, and oral epithelia in primate models. Examining the phenotype of mucosal lymphocytes is critical in understanding host susceptibility to HIV-1 infection. Indeed, certain characteristics of the mucosal compartment render it extremely permissive to HIV-1 infection and supportive of HIV-1 replication. Compared with circulating lymphocytes, a greater percentage of these mucosal CD4+ lymphocytes express the CCR5 chemokine coreceptor (Figure 2). The percentage of mucosal CD4+ cells that coexpress CCR5 and CXCR4 chemokine receptors is also substantially greater than that seen in the blood. Additionally, due to their proximity to the external environment and constant exposure to myriad food and microbial antigens, a predominant number of G1 mucosal CD4+ T cells are activated and well differentiated with a memory phenotype. Lastly, the G1 mucosa is maintained in a state of physiologic inflammation characterized by a high percentage of proinflammatory, HIV-1 stimulatory cytokines.

Effect of Simian Immunodeficiency Virus Infection on CD4+ T Cell Depletion in Simian Immunodeficiency Virus–Infected Macaques

The study of the human GI tract during acute HIV-1 infection is challenging. It is fraught with difficulties in identifying individuals during acute infection, and the added complexity of obtaining G1 biopsy specimens in the face of psychologic and physical complications associated with acute HIV-1 infection (Table 3). Consequently, initial work in this area emerged from the simian immunodeficiency virus (SIV)–macaque model. A striking depletion of intestinal CD4+ T cells was noted in macaques within days of SIV infection, at a time when little or no CD4+ T cell depletion was evident in the peripheral blood or lymph nodes (Figure 3). Furthermore, intestinal CD4+ T cell depletion occurred regardless of whether viral inoculum was intrarectally or intravenously delivered. These studies were subsequently extended to demonstrate that G1 lymphocyte depletion occurs in all stages of SIV infection, including acute infection. Recent data obtained from the SIV-macaque model provide startling insights into the degree of G1 CD4+ T-cell infection and depletion as well. Studies by Mattapallil and colleagues and Li and coworkers demonstrate rapid infection and destruction of G1 memory CD4+ T cells within days of infection with SIV. The former study suggests that, at peak viremia (day 10), as many as 60% of G1 memory CD4+ T cells may be infected with SIV and that these cells are lost within 14 days of infection. In contrast, Li and coworkers propose that CD4+ T-cell depletion is secondary to virus-triggered, Fas-Fas ligand–mediated apoptosis. It is likely that CD4+ T-cell destruction is multifactorial and is caused by virus-induced cytolysis and apoptosis, as well as by the host’s own cytotoxic T lymphocyte (CTL), natural killer (NK)–cell responses. Further work needs to be done to resolve this issue.

FIGURE 1. Organization of the Intestinal Immune System.
The first point of contact, especially since the dominant mode of HIV transmission worldwide is across mucosal surfaces.

Proximity to the external environment and constant exposure to antigens maintain resident cells in a state of "physiologic inflammation."

The GI mucosa has high levels of proinflammatory, HIV-1-stimulatory cytokines.

Dense clustering of cells within the GI mucosa, facilitating cell-to-cell transmission.

Large population of “preferred target cells” for HIV-1.
  * 40—70% of GI lymphocytes express CCR5 coreceptor.
  * Majority (>90%) of GI lymphocytes have memory phenotype, and a predominant population of these cells are effector memory cells.

GI indicates gastrointestinal.

**Effect of HIV Infection on CD4+ T Cell Depletion in Humans**

Studies conducted during the 1990s indicated that intestinal CD4+ T-cell depletion may be an early feature of HIV-1 infection as well, and that intestinal CD4+ T-cell depletion is more substantial than depletion of CD4+ T cells in the peripheral blood. However, such studies were not conducted in patients identified during acute infection. Along with 2 other groups, we have recently demonstrated that during acute HIV-1 infection, a preferential and profound depletion of CD4+ T cells occurs within the GI tract. In the first of these studies, Guadalupe and coworkers described 2 individuals with acute HIV-1 infection in which significant CD4+ T-cell depletion occurred within approximately 4 to 6 weeks of infection. Brenchley and colleagues studied 1 individual with acute HIV-1 infection (infected for <1 mo) and 4 individuals with early HIV-1 infection (duration of infection was 4–9 mo). In all 5 subjects, a preferential CD4+ T-cell depletion was noted in the intestines. In fact, significant GI CD4+ T-cell depletion was characteristic of all stages of HIV-1 infection.

Our initial focus was to describe changes within the GI tract of individuals with acute and early HIV-1 infection. To this end, 13 individuals identified during acute (n=7) and early (n=6) infection were studied. Mean CD4+ T-cell percentage in the GI tract was 15.7±3.6% compared with a mean of 42.3±14.7% (P<.001). Thus, in all subjects, profound CD4+ T-cell depletion was observed in the GI tract, and was significantly greater than depletion in the peripheral blood (P<.05) (Figure 4). Since then, we have extended our studies to 44 subjects with acute and early HIV-1 infection and have observed far greater CD4+ T-cell depletion in the intestines compared with the peripheral blood. Having demonstrated a striking CD4+ T-cell depletion within the GI tract, the subsets of CD4+ T cells where this depletion was most prominent were examined. Since a majority of intestinal CD4+ T cells express CCR5 and given that viruses, during the early stages of HIV-1 infection, are predominantly CCR5 tropic, it was not surprising that both Brenchley and colleagues and we, both observed GI lymphocyte...

depletion to be most prevalent among the ccr5+ subsets of cd4+ T cells. In addition, we have observed marked cd4+ T-cell depletion in the effector sites (lamina propria) of the g1 tract with relative sparing of the inductive sites (organized lymphoid tissue). In contrast, however, hiv-1 rna was localized to the inductive sites. This discrepancy may possibly be best explained by loss of target cells in the effector compartment. Hypothetically, if a subject could be examined within the first 7 to 10 days of infection, viral rna would be evident in the effector compartment as well, prior to the annihilation of the resident cd4+ cells.

**Mechanisms of Intestinal CD4+ T-Cell Depletion**

Recent data obtained from the siv-macaque model provide startling insights into the degree of g1 cd4+ T cell infection and depletion as well. The aforementioned studies by Mattapallil and Li, working with their colleagues, demonstrate rapid infection and destruction of g1 memory cd4+ T cells within days of infection with siv. As mentioned, the former study suggests that, at peak viremia (day 10), as many as 60% of g1 memory cd4+ T cells may be infected with siv and that these cells are lost within 14 days of infection. This results in profound immunodeficiency that begins within days of infection, not months to years as was previously thought. The authors put forth the notion that memory cd4+ T cells are killed by direct, virus-mediated destruction rather than by bystander effects or suppression of cd4+ T cell production. Li and coworkers showed, somewhat surprisingly, that g1 cells initially infected with cd4 have a nonactivated (cd69−cd25+Ki67+) phenotype. Peak infection of memory cd4+ T cells within the g1 tract corresponded to peak viremia, and depletion of g1 cd4+ T cells coincided with a drop in the peripheral viral load. The studies investigators therefore suggested the concept of “substrate depletion” resulting in viral load reduction in the host. In contrast to Mattapallil and coworkers, and as discussed above, the Li study authors propose that cd4+ T cell depletion is secondary to virus-triggered, fas-fas liga eff as by the host's own ctl, nk-cell responses.

Picker and coworkers have studied the relationship between mucosal and systemic cd4+ T-cell dynamics and disease progression. Rhesus macaques were infected with either ccr5-tropic sivmac239 or a ccr4-tropic variant of sivmac155t3. As expected, those infected with ccr5 tropic virus demonstrated profound depletion of tem cells associated with initial peak viremia of 10+ to 104 rna copies. Interestingly, this was followed by a prompt proliferative response in the cd4+ T-cell memory population, documented by both ki67 staining as well as accelerated decay of brdU labeling. Although macaques infected with ccr4-tropic virus had markedly high levels of peak viremia and rapid and profound drops in peripheral cd4+ T-cell counts, they were clinically indistinguishable from the remaining macaques. However, a subset of sivmac239-infected macaques progressed to simian aids within 200 days of infection. In these animals, the proliferative burst in the memory cd4+ T-cell population could not be sustained beyond day 42 of infection. It would therefore appear that lack of preservation of mucosal immunity is associated with early disease progression in this model. In addition, it would appear that the ability to maintain the proliferative burst of cd4+ memory T cells, presumably from either the naive T-cell or central memory population, is a key determinant in siv pathogenesis.

We have also explored putative virologic and immunologic factors associated with g1 cd4+ T-cell depletion and conclusively demonstrated, using PCR-based methods, that the HIV-1 viral burden—both proviral DNA and HIV-1 rna—is consistently greater in the g1 cd4+ T-cell population when compared with the peripheral blood cd4+ T cells (Figure 5). By combining in situ hybridization and immunohistochemistry, we found both activated and nonactivated cells expressing HIV-1 rna at days 18 to 19 postinfection.

Furthermore, high levels of virus in the g1 tract were observed to be associated with activation and proliferation of mucosal lymphocytes and a rather dramatic increase in cytotoxic cells, both cd8+ and cd8+. Levels of immune activation, as indicated by CD8 expression on T cells, has long been known to be a major prognostic indicator in patients infected with HIV-1, particularly in the era preceding highly active antiretroviral therapy (HaART). We have demonstrated that during acute and early infection.
FIGURE 4. The Preferential Depletion of Gastrointestinal CD4+ T Cells During Acute and Early HIV-1 Infection.

PBMCs and MMCs from the rectosigmoid region from subjects with acute and early HIV-1 infection (n=13), and uninfected controls (n=10) were analyzed by flow cytometry. CD3+ gated lymphocytes were analyzed for the expression of CD4 and CD8. (I) A representative flow plot is depicted. CD8+ T cells are shown on the x axis and CD4+ T cells are shown on the y axis. (II) Comparison of CD4+ T cells in the blood and GI tract of all 13 subjects with acute and early infection. The percent of CD4+ T cells is compared between blood (yellow) and gut (red) per study subject. (III) Immunohistochemical characterization of the immune effector and inductive sites in the rectal biopsies. (A) At a magnification of 25x, a Giemsa-stained section is shown depicting a lymphoid nodule (inductive site) where the CC and T are indicated. The effector compartment represented by the LP is seen in the lower part of the section. (B and C) The inductive sites are densely populated with CD4+ T cells (stained red) in subjects with both acute and early HIV-1 (B) and subjects who are uninfected (C) (shown at a magnification of 40x). (D and E) Effector sites in acute and early HIV-1 infection (D) show substantial depletion of CD4+ T cells (stained red) compared with uninfected controls (E) (shown at a magnification of 100x).

infection (AEI), there is a substantial increase in activated memory cells (CD45RO+/CD69+) within the GI tract (Figures 6 and 7). While this, in itself, is not surprising, the observation can have 2 potential consequences.

Firstly, most mucosal cells are terminally differentiated effector cells and are much more likely to apoptose when activated than are peripheral blood derived naïve cells. Therefore, given that about two-thirds of mucosal CD4+ T cells express markers of activation (CD38) during acute infection, it is likely that activation-induced cell death plays an important role in GI CD4+ T-cell depletion in this setting. Secondly, activated CD4+ T cells represent the “preferred cellular targets” for HIV-1.14,45 Thus, it would appear that HIV-1 infection generates an expanding population of cellular targets within the GI tract by triggering activation of densely packed mucosal mononuclear cells (Figure 7).

Based on these observations, we have proposed that mucosal CD4+ T-cell depletion during AEI is multifactorial, and is due to (although not limited to) a combination of direct viral infection, activation-induced cell death, and host-derived cytotoxic cellular response. During acute and early infection with HIV-1, GI CD4+ lymphocytes are believed to be preferentially infected and have a greater viral burden compared with PB CD4+ lymphocytes (Figure 7). Although our studies represent snapshots of postepidemic events, the fact that up to 102-fold–greater HIV-1 RNA levels were observed in GI CD4+ T cells compared with PB CD4+ T cells is consistent with the concept that the GI tract preferentially supports early events during acute infection. This is likely due to the presence of densely clustered memory CD4+ T cells expressing high levels of CCR5 in the GI tract (Figure 7).46,47

**The Effect of Antiretroviral Therapy on Gastrointestinal Immune Reconstitution**

The development and evolution of HAART has resulted in the ability to achieve durable control of viral replication and preservation of immune function in the majority of treated subjects with relatively simple and minimally toxic treatment regimens.36-51 Given that the GI tract harbors the largest collection of immune cells in the body, it is critical to assess for immune reconstitution with antiretroviral therapy in this compartment. However, there are rather conflicting and limited data on the reconstitution of the GI immune system with potent antiretroviral therapy, particularly when treatment is initiated during acute and early HIV-1 infection.

Guadalupe and coworkers have reported that, of 2 patients treated during primary HIV-1 infection, near complete mucosal reconstitution occurred in 1 subject whereas the second showed incomplete restoration despite 5 years of antiretroviral therapy.37 The same group concluded from the study of SIV-infected macaques that CD4+ T-cell reconstitution in the GI tract could be achieved to near-complete levels if antiretroviral therapy was initiated during primary SIV infection, but not later.38 Eight patients studied cross-sectionally 6 months to 5 years after the initiation of therapy during acute and early infection suggested that, despite therapy, CD4+ T cell depletion persisted in the GI mucosa.39 To conclusively address this issue, we undertook a comprehensive study to determine the effects of antiretroviral therapy initiated during acute and early HIV-1 on reconstitution of the GI immune system. We prospectively followed 18 individuals identified and treated during AEI, and performed serial rectosigmoid biopsies prior to and up to 32 months posttreatment initiation. In addition, cross-
Figure 7. Proposed Model of Immune CD4+ T-cell Depletion in the Gastrointestinal Tract During Acute and Early HIV-1 Infection.

The sequence of events that culminate in profound mucosal CD4+ T cell depletion are depicted in a series of 4 panels here. Panel I shows a simplified representation of lamina propria lymphocytes separated from the intestinal lumen by a single layer of epithelial cells. CD4+ T cells are shown in pink and CD8+ T cells in blue. We have emphasized dense clustering of lymphocytes in close proximity to the external environment here. Panel II shows HIV in the intestinal lumen and lamina propria. On the left side of the panel, a virion fusing with a CD4+ T cell membrane is depicted. In panel III, lamina propria CD4+ T cells are shown producing virus particles at peak viremia. Panel IV shows the sequelae of primary HIV-1 infection with emphasis on the profound loss of intestinal CD4+ T cells.

Images and virus models created by Louis E Henderson, PhD.
sectional studies were performed on a total of 22 individuals who were also treated during AEI. This study demonstrated that in 70% of the cohort, CD4+ T cells did not reconstitute in the lamina propria of the GI tract despite uninterrupted, apparently suppressive antiretroviral therapy for up to 5 to 7 years. Based on immunohistochemistry, it was estimated that approximately 50% to 60% of lamina propria CD4+ T cells remain depleted when compared with uninfected controls (Figure 8).

Within the GI tract, there appears to be subcompartmental variation: immune inductive sites reconstitute better and resemble peripheral blood lymphocyte subsets when compared with the immune effector sites (Figure 8). CD4+ T cells expressing the CCR5 receptor or dually expressing the CCR5/CXCR4 receptors were the cell populations most severely affected. Accompanying this persistent lesion were increased levels of activated CD4+ and CD8+ T cells within the GI tract.

**Figure 8.** Persistent Depletion of CD4+ T Cells in the Majority of Patients Despite Long-term, (Apparently) Suppressive Antiretroviral Therapy. Immunohistochemical characterization of immune-inductive and effector sites in rectal biopsies. (A) CD4+ T cells per unit area were determined in organized lymphoid tissue (immune inductive sites, left panel) and LP (immune effector sites, right panel). Mean CD4+ T cell numbers were compared between HIV-uninfected (red boxes), acute and early infection (green boxes), and patients treated for up to 1 y (blue boxes), 1-3 y (brown boxes), and 3-7 y (purple boxes). In these plots, the boxes extend from the first to the third quartiles, enclosing the middle 50% of the data. The middle line within each box indicates the median of the data, whereas the vertical line extends from the 10th to the 90th percentile. Means of the data are represented by filled-in squares. (B) A biopsy section (viewed at 40x magnification) from an uninfected control participant, showing CD4+ T cells (stained red) within the GI lamina propria (panel I). In contrast, a pronounced reduction in LP CD4+ T cells is noted in a patient with acute and early HIV-1 in panel II, which does not correct despite antiretroviral therapy for 2 y in the same patient (panel III). Another representative study patient is presented, where LP CD4+ T-cell depletion during acute and early HIV-1 (panel IV) does not correct after antiretroviral therapy for 1 y (panel V).

AEI indicates acute and early infection; LP, lamina propria; GI, gastrointestinal.

Consequences of Persistent Mucosal Depletion During Antiretroviral Therapy

At this point in time, the consequences of persistent CD4+ T-cell depletion in the GI tract are unknown. It is clear that the largest reservoir of immune cells’ shows a unique profile of CD4+ T-cell reconstitution during HAART. In the pre-HAART era, opportunistic mucosal infections were a common feature of disease progression. With treatment, it is evident that patients do not demonstrate any short-term effects of having a 50% loss of CD4+ T cells in the GI lamina propria. It is possible that sufficient redundancy in the immune system prevents adverse outcome in patients with chronic HIV-1 infection. However, it is important to recognize that given the projected long-term survival of patients with HIV-1, considerable loss of mucosal CD4+ T cells could accelerate immune senescence with attendant consequences. In recent clinical studies, an increased incidence of polyps and colorectal malignancies has been observed in individuals infected with HIV-1 independent of antiretroviral therapy. These studies were confined to a single site and describe a homogenous cohort of US veterans. Definitive studies are needed to assess the impact of persistent depletion of GI immune cells on the incidence of colorectal polyps and malignancies.

Conclusions

A number of important conclusions emerge from the recent studies examining the GI tract during acute and chronic HIV-1 infection (Table 4):

1. First and foremost, it is clear that the GI tract is targeted during all stages of HIV-1, and this is especially so during AEI. We and others have documented that CD4+ T cells are preferentially lost from the GI tract within weeks of HIV and SIV infections. Recent data have demonstrated that GI CD4+ T-cell depletion is also observed in natural hosts of SIV—the sooty mangabees and African green monkeys. Therefore, both pathogenic (HIV-1 infection in man and SIV infection in rhesus macaques) as well as nonpathogenic (SIV infection in sooty mangabees and African green monkeys) lentiviral infections are characterized by depletion of GI CD4+ T cells during acute and early infection. This would suggest that the GI tract is critical in establishment of such infections in a new host. The subsequent role played by the GI tract in disease pathogenesis remains an area of active investigation.

2. The mechanisms of GI CD4+ T-cell depletion are probably complex and multifactorial—direct and indirect viral cytopathicity, host-derived cellular immune response, activation-induced cell death and, perhaps, alterations in mucosal homing are all responsible.

3. Despite long-term antiretroviral therapy, CD4+ T-cell reconstitution remains deficient in the GI tract in spite of the reconstitution seen in the peripheral blood.

4. In the short term, patients appear to be asymptomatic. However, vigilance for increased risk of infections, polyps, and malignancies is warranted in the long term, especially as the longevity of HIV-1-infected individuals increases.

5. With regard to preventive efforts directed against HIV-1, recent data underscore the need to develop strategies to protect mucosal surfaces from infection. The use of microbicides and CCR5 blockers represents such interventions.

6. Finally, and perhaps most importantly, these findings re-emphasize the fact that mucosal immune responses must be targeted in the development of effective HIV-1 vaccines.
